Coordination and navigation of heterogeneous MAV–UGV formations localized by a ‘hawk-eye’-like approach under a model predictive control scheme

Martin Saska¹, Vojtěch Vonásek¹, Tomáš Krajník² and Libor Přeučil¹

Abstract
An approach for coordination and control of 3D heterogeneous formations of unmanned aerial and ground vehicles under hawk-eye-like relative localization is presented in this paper. The core of the method lies in the use of visual top-view feedback from flying robots for the stabilization of the entire group in a leader–follower formation. We formulate a novel model predictive control-based methodology for guiding the formation. The method is employed to solve the trajectory planning and control of a virtual leader into a desired target region. In addition, the method is used for keeping the following vehicles in the desired shape of the group. The approach is designed to ensure direct visibility between aerial and ground vehicles, which is crucial for the formation stabilization using the hawk-eye-like approach. The presented system is verified in numerous experiments inspired by search-and-rescue applications, where the formation acts as a searching phalanx. In addition, stability and convergence analyses are provided to explicitly determine the limitations of the method in real-world applications.

Formation control, model predictive control, unmanned aerial vehicles, unmanned ground vehicles, trajectory planning, obstacle avoidance, receding horizon control

1. Introduction
Precise relative localization within large teams of unmanned vehicles is required in real-world search-and-rescue (SAR) missions, where a multi-robot system has to cooperatively explore large areas in a short time. In these tasks, robots may not rely on a pre-installed global localization infrastructure, which is usually not available, or is damaged, in sites under SAR exploration. Systems available worldwide (like GPS) lack the required precision for compact formations of small robots, and lose reliability in urban and indoor environments. A common solution is to use systems of relative localization carried onboard autonomous vehicles. This approach brings additional movement constraints to the robotic team, which have to be integrated into the formation control and stabilization.

In this paper, we present a formation-driving approach adapted for onboard visual relative localization of heterogeneous teams of unmanned helicopters (quadrotors) and ground robots. The localization is based on simple lightweight bottom cameras mounted on unmanned micro aerial vehicles (MAVs). Identification patterns for the localization are placed on both the unmanned ground vehicles (UGVs) and the MAVs. With this top-view approach, the problem of loss of direct visibility can be tackled better. Such a problem occurs if systems of visual relative localization are employed for ground robots operating in a workspace with scattered objects/obstacles, as is common in SAR scenarios. The possibility of localizing robots from the top view increases robustness and precision in determining the relative position. Additionally, the top view brings another perspective for human operators supervising the mission. MAVs may also complement the team of UGVs with their ability to visit/search places inaccessible to ground vehicles, as we demonstrated in Saska et al. (2012b). For more opportunities and advantages to MAVs, see the survey in Kumar and Michael (2012).

The proposed MAV–UGV stand-alone system provides a lightweight, low-cost and efficient solution, which may act
as an enabling technique for extensive utilization of simple micro-scale robots in demanding scenarios. This article focuses on theoretical and implementation aspects of the formation-driving mechanism suited for the real-world deployment of autonomous robots relying on top-view relative localization (in this paper referred to as the hawk-eye concept). Technical details on the visual relative localization of team members from ‘flying cameras’ are omitted, but they are available in Saska et al. (2012a). The main contribution of the work presented here lies in the proposed incorporation of the hawk-eye concept into formation control and its shape stabilization. The idea of using the hawk-eye relative localization of team members requires new formation-driving and robot control approaches that are presented in the rest of the paper.

The aim of our research effort is to enable the deployment of closely cooperating groups of MAVs outside laboratories equipped with precise motion-capture systems (e.g. the Vicon system) and, on the basis only of relative localization, to achieve the same results obtained using these systems nowadays (Turpin et al., 2011; Kushleyev et al., 2012; Mellinger et al., 2012).

1.1. State-of-the-art methods and progress beyond the current formation-driving approaches

Formation-driving algorithms can be divided into three main approaches: virtual structures (Beard et al., 2001; Ren, 2008; Michael and Kumar, 2009; Ghommam et al., 2010; Liu and Jia, 2012), behavioral techniques (Langer et al., 1994; Lawton et al., 2003; Olfati-Saber, 2006), and leader–follower methods (Desai et al., 2001; Fredslund and Mataric, 2002; Das et al., 2003; Mastellone et al., 2008; Sira-Ramiandrez and Castro-Linares, 2010; Yang et al., 2010; Klančar et al., 2011; Min and Papanikolopoulos, 2012). For further references on distributed robotic control see Bullo et al. (2009). In our work, we consider a modification of the leader–follower method, in which all robots (MAVs and UGVs) of the formation follow a virtual leader. Formation stabilization is achieved by sharing knowledge of the virtual leader’s position within the formation.

Recently, research endeavor in the formation-driving community has been aimed mainly at tasks of formation stabilization (Hengster-Movrić et al., 2010; Dong, 2011; Liu and Jia, 2012) and formation following a predefined path (Xiao et al., 2009; Ghommam et al., 2010; Sira-Ramiandrez and Castro-Linares, 2010; Do and Lau, 2011). For example, in Dong (2011), the task of formation stabilization and convergence to a desired pattern is tackled for formations with communication delays. In Hengster-Movrić et al. (2010), a multi-agent control system using an artificial potential based on bell-shaped functions is proposed. In Liu and Jia (2012), a distributed iterative learning scheme is employed for solving formation control with a switching strategy in the virtual structure and virtual leader–follower schemes.

The path-following problem is tackled by designing a nonlinear formation control law in Ghommam et al. (2010). The method based on the virtual structure approach uses propagation of a virtual target along the path. In Do and Lau (2011), path-following is investigated for groups of robots with a limited sensing range. In Sira-Ramiandrez and Castro-Linares (2010), according to the leader–follower concept, the leader robot is forced to follow a given path, while the followers track the leader’s path with a fixed time delay. In Xiao et al. (2009), in addition to trajectory tracking, the autonomous design of a desired geometric formation pattern is discussed.

In addition to methods of formation driving for UGVs, we should mention some approaches designed for unmanned aerial vehicles (UAVs) (Saffarian and Fahimi, 2009; Burdakov et al., 2010; Abdessameud and Tayebi, 2011; Liu et al., 2011; No et al., 2011). In No et al. (2011), the formation stabilization and desired-shape-keeping are treated as a dynamic 3D tracking problem. The relative geometry of multiple UAVs is kept via a cascade-type guidance law under the leader–follower concept. A leader–follower approach for stabilizing helicopter formations using a nonlinear model predictive control (MPC) is proposed in Saffarian and Fahimi (2009). This method is optimized for an online embedded solution enabling a response to the fast dynamics of UAVs in Liu et al. (2011). In Burdakov et al. (2010), UAVs in a static formation form relay chains for communication in surveillance applications. The formation stabilization of the vertical take-off and landing of UAVs in the presence of communication delays is addressed in Abdessameud and Tayebi (2011). Finally, let us mention Tanner and Christodoulakis (2007), who consider a heterogeneous team of UAVs and UGVs. The aim of the approach is to stabilize a formation of UAVs above UGVs in circular orbits using interconnections of UAV and UGV groups via ground-to-air-only communication.

In most of the approaches cited above, it is supposed that the desired trajectory followed by the formation is designed by a human operator or by a standard path-planning method modified for the formation requirements. The method presented in this paper goes beyond these works. It does not rely on following a given trajectory, as in most of the state-of-the-art methods. The global trajectory planning is directly integrated into the formation control mechanism. This is necessary for finding a feasible solution for the hawk-eye concept, where the constraints of direct visibility have to be satisfied. Direct incorporation of trajectory planning and formation stabilization enables effective operation of the group in an environment with obstacles, while the hawk-eye relative localization is ensured.

In the literature, direct inclusion of trajectory planning in formation driving is rarely found. To the best of our knowledge, we can mention only the leader–follower approach based on potential fields presented in Garrido et al. (2011) as an appropriate example. This algorithm enables both formation stabilization and navigation of the formation into
a desired goal. Although the method provides interesting results and seems to be computationally inexpensive, it has been developed for ground holonomic robots, and it suffers from the usual problems of algorithms inspired by potential fields. The authors state that their method behaved correctly in spite of the suddenly changed direction of movement around the sequence of points given by the planning method. However, it would be difficult to explicitly involve follower mobility constraints for a formation of nonholonomic robots. Further research would also be necessary to incorporate the requirements of 3D formations, and in particular the constraints given by the relative visual localization as proposed in the method presented here. Therefore, this method cannot be used for direct comparison with results achieved in this paper.

Finally, we should mention the paper by Dorigo et al. (2013), which is similar to our work in terms of deployment of eye-bots on the ceiling with the aim of providing a bird’s-eye view. In Dorigo et al. (2013), the eye-bots are not moving together with ground robots if the top-view localization is in operation; they are fixed with the ceiling. Therefore, the motion coordination and formation driving of heterogeneous teams do not need to be solved there.

### 1.2. State-of-the-art methods and progress beyond the current MPC approaches for formation control

In our method, we rely on MPC. This allows us to involve constraints imposed by vehicles (mobility constraints), by obstacles (environment constraints), and by inter-vehicle relations into the formation driving. The inter-vehicle relations are specified mainly by the shape of the formation feasible for the hawk-eye-like relative localization.

The MPC approach is often used for stabilization of non-linear systems with control constraints. In Saffarian and Fahimi (2009) and Liu et al. (2011), it was shown that the computational power of microprocessors available onboard unmanned helicopters enables the employment of MPC techniques also for the formation control of these highly dynamic systems, as is proposed here.

For descriptions and for a general survey of MPC methods, see Barambones and Etxebarria (2000), Mayne et al. (2000) and Alamir (2006) and the references therein. Early works applying MPC to formation control are presented in Dunbar and Murray (2006) and Franco et al. (2008). These papers utilized MPC for formation forming in a workspace without obstacles. Recently, researchers have taken advantage of MPC to respond to changes in a dynamic environment, again, mainly in tasks including path tracking and formation stabilization (Saffarian and Fahimi, 2009; Shin and Kim, 2009; Chen et al., 2010; Defoort, 2010; Zhang et al., 2010; Liu et al., 2011; Chao et al., 2012). In Chao et al. (2012), the authors introduce a new cost penalty into MPC optimization to guarantee obstacle avoidance. A priority strategy is employed to ensure inter-vehicle collision avoidance. In Defoort (2010), a decentralized receding horizon motion planner is developed to coordinate robots using neighbor-independent planning. This is followed by adjusting the plans with inter-team collisions using locally exchanged information. The trajectory tracking mechanism developed in Zhang et al. (2010) is based on integrating a differential evolution algorithm into the MPC concept. In Shin and Kim (2009), a heuristic approach is developed to reduce the required computational time of MPC iterations and to enable path tracking with an obstacle-avoidance function. Formation stabilization on a pre-computed path based on the MPC leader–follower concept is presented in Chen et al. (2010).

In our approach, we go beyond these works in several aspects. We apply the MPC technique to the stabilization of followers in the desired positions behind the leader, as well as to the trajectory planning into a desired goal area. We propose a new MPC concept combining the trajectory planning into the desired goal region and the immediate control of the formation in a single optimization process. The method can continuously respond to changes in the vicinity, while keeping the cohesion of the immediate control inputs with the directions of movement of the MAV–UGV formation in the future. Furthermore, we propose a novel obstacle-avoidance function for multi-vehicle trajectory planning. The avoidance function respects the restrictions of the proposed hawk-eye concept.

The paper is structured as follows. The problem statement is summarized in Section 2. In Section 3, necessary preliminaries are given. The novel methodology is described in Section 4, focusing on the utilization of a heterogeneous formation of UGVs and MAVs under the hawk-eye concept. A proof of the convergence of the formation into the desired target region, together with a discussion on the assumptions necessary to ensure formation stability under the hawk-eye relative localization, is shown in Section 5. Numerical and hardware experiments are presented in Section 6, which is followed by our conclusions in Section 7. A discussion on a controller for the Ar.Drone, which was designed to enable integration of the drone into the proposed MPC formation stabilization scheme, can be found in the Appendix. For clarification purposes, lists of variables used in this paper are summarized in Tables 1 and 2.

The basic ideas of the planning for heterogeneous MAV–UGV formations under hawk-eye relative localization were presented in a conference paper (Saska et al., 2012c), which is extended here. In comparison with Saska et al. (2012c), we provide here a more comprehensive description of the method, accompanied by the proof of convergence. An additional extension is the real-world experiment and numerical analysis verifying the robustness of the proposed methodology.

2. Problem statement

In this paper, we consider the formation-driving problem in scenarios motivated by SAR applications. We are interested in scenarios where a team of robots has to reach a desired target region or a sequence of target regions given by a
supervising expert. During the movement between these given areas, the robots have to keep a fixed-shape formation satisfying the mission requirements. The robots can form a searching phalanx (a line formation) to be able to search for victims in large areas or they can form a compact fleet of vehicles (a formation of a general shape) for transportation purposes.

We assume a group of simple ground nonholonomic robots without any onboard sensors for their localization. In addition, we assume a group of unmanned MAVs (quadrotors) equipped with a bottom camera and an image-processing system (Saska et al., 2012a). The image-processing system provides information on the relative position between the camera and the center of an identification pattern. The patterns are carried by all UGVs and MAVs except the one flying at the highest altitude. We assume that one of the robots (UGV or MAV) is equipped with a global localization (e.g. the vision-based navigation in Krajník et al., 2010). The precision and reliability of the system and the utilized platform. Moreover, we assume that the required relative distances between the robots are significantly bigger than the precision of the robots in a compact formation. The precision and reliability of the position of the formation in the map, but it is not sufficient for the coordination of the robots in a compact formation.

We assume that the required relative distances between the robots are significantly bigger than the precision of the visual relative localization. The precision of the employed system (described in Saska et al., 2012a) is \( \sim 1\) cm. Therefore the minimal allowed distance between the robots is 10 cm in the experiments. Between two UAVs, the spacing usually has to be enlarged, due to airflow effects that depend on the utilized platform. Moreover, we assume that the shape of the formation is designed in such a way that all robots, except the MAV follower flying at the highest altitude, are in the field of view of at least one of the bottom cameras mounted on the MAVs.

In the assumed scenario, the map of the environment is partly known by all robots. The group is capable of detecting unknown and dynamic obstacles using their onboard sensors. These updates of the map are shared by the robots via WiFi communication. The position of the target region or a sequence of target regions and the desired shape of the formation are also known.

In this paper, we solve the task in which the 3D formations of MAVs and UGVs have to reach a target region or a sequence of target regions, while the requirements given by hawk-eye relative localization are satisfied. This means that direct visibility between the vehicles has to be maintained during deployment of the formation.

3. Preliminaries

Let \( \psi_j(t) = \{x_j(t), y_j(t), z_j(t), \phi_j(t)\} \in C \), with \( j \in \{L, 1, \ldots, n_r\} \), denote configurations of a virtual leader \( L \) and \( n_r \) followers at time \( t \). The virtual leader is positioned in front of the formation and on the axis of the formation, which is important for the symmetric obstacle avoidance function. \( C \) is the configuration space of the robots. The Cartesian coordinates \( x_j(t), y_j(t), \) and \( z_j(t) \) define the positions \( \vec{p}_j(t) \) of the robots, and \( \phi_j(t) \) denotes their heading. All MAVs and UGVs are denoted as followers in the approach presented here. For the MAVs, the heading \( \phi_j(t) \) directly becomes the yaw (see Figure 1 for the coordinates system of the MAVs). The roll and the pitch do not need to be included directly in the kinematic model employed in the MPC. They depend on the velocity and the turning curvature, as shown for a quadrotor helicopter in the Appendix.

Let us assume that the environment of the robots contains a finite number \( n_o \) of compact obstacles \( a_l, \ l \in \{1, \ldots, n_o\} \). The configuration space \( C \) can then be divided into two segments: \( C_{obs} \), representing the configurations of the robots colliding with an obstacle, and \( C_{free} \), representing the subspace of the feasible configurations as \( C_{free} = C \setminus C_{obs} \).

**Definition 3.1. (Target region.)** Let us define a target region \( S_F \) as a convex compact region such that, for any robot with position \( \vec{p}_j(\cdot) \in S_F \), the relation \( \psi_j(\cdot) \in C_{free} \) is satisfied.

The kinematics for any robot \( j \) in 3D is described by the following simple nonholonomic kinematic model:

\[
\begin{align*}
\dot{x}_j(t) &= v_j(t) \cos \phi_j(t) \\
\dot{y}_j(t) &= v_j(t) \sin \phi_j(t) \\
\dot{z}_j(t) &= w_j(t) \\
\dot{\psi}_j(t) &= K_j(t) v_j(t)
\end{align*}
\]

Forward velocity \( v_j(t) \), curvature \( K_j(t) \), and ascent velocity \( w_j(t) \) represent control inputs denoted as \( \vec{u}_j(t) = \{v_j(t), K_j(t), w_j(t)\} \). For UGVs (in the presented results for car-like robots), these control inputs can be directly employed for steering them. (We assume that UGVs operate on a flat surface and that \( z_j(\cdot) = 0 \) and \( w_j(\cdot) = 0 \) for each of the UGVs.) In case of MAVs, \( v_j(\cdot), K_j(\cdot) \), and \( w_j(\cdot) \) values are inputs for the controller shown in the Appendix.

Let us now define a time interval \( [t_0, t_{end}] \) containing a finite sequence of elements of increasing time \( \{t_0, t_1, \ldots, t_{end-1}, t_{end}\} \), such that \( t_0 < t_1 < \ldots < t_{end-1} < t_{end} \).
The control inputs are held constant in each time interval \([t_k, t_{k+1})\), where \(k \in \{0, \ldots, \text{end} - 1\}\). From this point we may refer to \(t_k\) by using its index \(k\). By integrating the kinematic model over the interval \([t_0, t_{\text{end}}]\), we can derive the following model for transition points at which the control inputs change:

\[
x_y(k + 1) = x_y(k) + \frac{1}{K_L(k + 1)} \left[ \sin(\varphi(k) + K_L(k + 1)\Delta t(k + 1)) - \sin(\varphi(k)) \right], \quad \text{if} \quad K_L(k + 1) \neq 0;
\]

\[
y_y(k + 1) = y_y(k) + \frac{1}{K_L(k + 1)} \left[ \cos(\varphi(k) + K_L(k + 1)\Delta t(k + 1)) - \cos(\varphi(k)) \right], \quad \text{if} \quad K_L(k + 1) \neq 0;
\]

\[
z_y(k + 1) = z_y(k) + w_y(k + 1)\Delta t(k + 1)
\]

\[
\varphi_y(k + 1) = \varphi_y(k) + K_y(k + 1)\Delta t(k + 1)
\]

where \(x_y(k), y_y(k), \text{and} \ z_y(k)\) are Cartesian coordinates and \(\varphi_y(k)\) is the heading angle at the transition point with index \(k\) for any robot \(j \in \{L, 1, \ldots, n_r\}\). The sampling time \(\Delta t(k + 1)\) may not be uniform in the whole interval \([t_0, t_{\text{end}}]\), as shown below. The control inputs \(v_y(k + 1), K_y(k + 1)\), and \(w_y(k + 1)\) are constant between the transition points with indexes \(k + 1\) and \(k\). For each follower \(i \in \{1, \ldots, n_r\}\), the control inputs are limited by vehicle kinematic constraints (i.e. implied by the steering limitations and the drive system) as \(v_{\text{min},i} \leq v_i(k) \leq v_{\text{max},i}\), \(|K_i(k)| \leq K_{\text{max},i}\) and for the MAVs also \(w_{\text{min},i} \leq w_i(k) \leq w_{\text{max},i}\). These values may differ for each of the followers.

Finally, we need to define a spherical detection boundary with radius \(r_s\) and a spherical avoidance boundary with radius \(r_a\), where \(r_s > r_a\). Single robots should not respond to obstacles detected outside the region with radius \(r_a\). On the contrary, a distance between the robots and obstacles of less than \(r_s\) is considered inadmissible.

### 3.1. Formation-driving concept

The shape of the entire formation is maintained by a leader–follower technique based on the method presented in Barfoot and Clark (2004). The approach in Barfoot and Clark (2004) was designed for formations of UGVs working in a planar environment. Later, it was employed in an airport snow-shoveling project by formations of autonomous ploughs in Hess et al. (2009) and Saska et al. (2011). Here, we extend the notation from Barfoot and Clark (2004) to 3D.

In the proposed method, both types of followers, MAVs and UGVs, follow the same trajectory of the virtual leader in distances defined in the \(p, q, h\) curvilinear coordinate system, as visualized in Figure 1(a). The position of each follower \(i\) is uniquely determined: 1) by states \(\psi_i(t_{pi})\) in the traveled distance \(p_i\) from the actual position of the virtual leader along the leader’s trajectory; 2) by the offset distance \(q_i\) from the trajectory in the perpendicular direction; and 3) by the elevation \(h_i\) above the trajectory. Note that \(p_i\) denotes the time when the virtual leader was at the traveled distance \(p_i\) behind the actual position.

To convert the state of the followers in curvilinear coordinates to a state in Cartesian coordinates, the following equations can be applied:

\[
x_i(t) = x_i(t_{pi}) - q_i\sin(\varphi_L(t_{pi}))
\]

\[
y_i(t) = y_i(t_{pi}) + q_i\cos(\varphi_L(t_{pi}))
\]

\[
z_i(t) = z_i(t_{pi}) + h_i
\]

\[
\varphi_i(t) = \psi_i(t_{pi})
\]

where \(\psi_i(t_{pi}) = \{x_i(t_{pi}), y_i(t_{pi}), z_i(t_{pi}), \varphi_i(t_{pi})\}\) is the state of the virtual leader at time \(t_{pi}\).

The virtual leader has no constraints given by its mechanical capabilities. It is a virtual point, but it must respect the constraints of the guided formation. For the virtual leader, the admissible control set can be determined by applying the leader–follower approach as

\[
K_{\text{max},i} = \min_{i = 1, \ldots, n_r} \left( \frac{K_{\text{max},i}}{1 + q_iK_{\text{max},i}} \right)
\]

\[
K_{\text{min},i} = \max_{i = 1, \ldots, n_r} \left( -\frac{K_{\text{max},i}}{1 - q_iK_{\text{max},i}} \right)
\]

\[
v_{\text{max},i}(t) = \min_{i = 1, \ldots, n_r} \left( \frac{v_{\text{max},i}}{1 + q_iK_i(t)} \right)
\]

\[
v_{\text{min},i}(t) = \max_{i = 1, \ldots, n_r} \left( \frac{v_{\text{min},i}}{1 - q_iK_i(t)} \right)
\]

\[
w_{\text{max},i} = \min_{i = 1, \ldots, n_r} \left( w_{\text{max},i} \right)
\]

\[
w_{\text{min},i} = \max_{i = 1, \ldots, n_r} \left( w_{\text{min},i} \right)
\]

These restrictions must be applied to satisfy different values for the curvature and the speed of the robots in different
positions within the formation. Intuitively, the robot following the inner track during turning goes more slowly but with a bigger curvature than the robot further from the center of the turning. The equations arise from the fact that the followers turn around the same instantaneous center of curvature (ICC) and at the same angular speed. These restrictions ensure that the formation remains compact while turning.

The common ICC implies that robots with different positions within the formation have to turn with different curvatures. Therefore, the limits on the curvature of the leader’s trajectory must ensure that all of the robots are capable of following a curvature that depends on their position within the formation. The constant angular speed of robots turning with a different curvature forces the followers to move at different velocities to be able to pass the curve at the same time. Again, the limits on the leader’s velocity must ensure that all of the robots are capable of going at the velocity that is determined by their position within the formation.

4. Integrated trajectory planning and formation stabilization under the hawk-eye concept

4.1. Method overview

The proposed formation-driving system is divided into two blocks: see the scheme depicted in Figure 2. In the Virtual Leader part, the Trajectory Planning block provides the complete trajectory into the target region for the virtual leader. The result is feasible for the entire formation and respects the requirements of the hawk-eye localization via the model of the formation. For this trajectory planning and control task, we have developed a novel method based on the MPC. The standard MPC solves a finite horizon optimization control problem for the system represented by the kinematic model. The MPC plan starts from the current states over the time interval $[t_0, t_0 + n \Delta t]$. This interval is known as the control horizon. The sampling time $\Delta t$ between the $N$ transition points is constant in this interval. We denote this horizon as $T_N$. We have extended this standard scheme with an additional time interval $[t_0 + N \Delta t, t_0 + (N + M) \Delta t]$. This planning horizon is used for planning the trajectory of the leader into the desired target region. The time difference between the $M$ transition points is variable in this time interval, which is denoted by $T_M$. This planning algorithm respects the constraints given by the desired shape of the formation, by the hawk-eye localization, and by the kinematics of the followers. In our approach, the entire horizon is divided into two segments: 1) the control horizon with a constant sampling rate used to obtain a refined immediate control, and 2) the planning horizon, where the time differences between the transition points are also variables that take part in the planning problem. Details on the construction of the horizons, with emphasis on the incorporation of the 3D formation, are presented in Section 4.3.

The resulting trajectory obtained in the Trajectory Planning block is described by a sequence of configurations of the virtual leader $\psi_k(t)$, $k \in \{1, \ldots, N + M\}$, and by constant control inputs applied in the intervals between the transition points. According to the MPC concept, only a portion of the computed control actions is applied. This utilized interval, $[t_0, t_0 + n \Delta t]$, is known as the receding step. In the next planning step, this process is repeated on the interval $[t_0 + n \Delta t, t_0 + n \Delta t + N \Delta t]$ as the finite horizon moves by the time steps $n \Delta t$, yielding a state feedback control scheme strategy. The output trajectory is used as an input for the Formation Driving module in the proposed system. In this module, the plan is transformed to the desired configurations of the followers (using equation (3)). Additionally, the plan is adapted for re-initialization of the optimization in the next planning step.

The core of the second main block is the Trajectory Following module. This part enables the design of appropriate collision-free control inputs for each of the MAV and UGV followers. It is responsible for avoiding impending collisions with obstacles or with other members of the team, and it corrects deviations from the desired trajectory provided by the virtual leader. Again this is ensured by the MPC concept using the actual data (states of neighbors and the map) which is shared within the team. Details on the control of followers can be found in Section 4.4.

4.2. Convex hull representing the formation in the trajectory planning

An important issue, which arises with the trajectory planning for heterogeneous 3D formations using the hawk-eye relative localization, is the need to design a valuable representation of the entire group. The aim of the representation is to incorporate the requirement of direct visibility between the robots into the concept of the trajectory planning with obstacle avoidance and formation stabilization functionalities.

We propose modeling the entire shape of the 3D formation defined in curvilinear coordinates with a convex hull of points representing the positions of the followers. The points are obtained by projecting the followers’ positions into the plane, which is orthogonal to the trajectory of the virtual leader in its actual position (see Figure 3). To describe how to acquire these points, let us define a coordinate system $\{x^i; y^i\}$ in this plane, as sketched in Figure 4. The projection of the $i$th follower’s position can then be obtained as $x^i := q_i$ and $y^i := h_i$. The convex hull of the set of points $\{x^i; y^i\}$, $i \in \{1, \ldots, n_r\}$, is an appropriate representation of the 3D formation in the proposed leader-follower constellation for two reasons: 1) Each follower $i$ intersects the plane orthogonal to the trajectory of the virtual leader at the point $\{x^i; y^i\}$ in the future. 2) The convex hull of this set of points denotes the borders of the area that should remain obstacle-free. It ensures the direct visibility
between MAVs and UGVs that is crucial for the presented formation-driving using the hawk-eye localization.

Moreover, for the obstacle-avoidance function presented in Section 4.3, the convex hull needs to be dilated by the detection boundary radius $r_d$. This ensures that obstacles are kept at a sufficient distance from the followers. An example of the dilated convex hull (DCH) of a formation is depicted in Figure 4.

**4.3. Trajectory planning and control for the virtual leader**

As mentioned above, we propose solving, in a single optimization step, two problems that are usually separated: long-term trajectory planning feasible for the formation, and computation of the immediate control sequences. To define the trajectory planning problem over the two time intervals (the control horizon and the planning horizon) in a compact form, we need to gather states $\psi_1(k)$, where $k \in \{1, \ldots, N\}$, and $\psi_2(k)$, where $k \in \{N+1, \ldots, N+M\}$, into vectors $\psi_{1N} \in \mathbb{R}^{4N}$ and $\psi_{1M} \in \mathbb{R}^{4M}$. Similarly, the control inputs $\bar{u}_1(k)$, where $k \in \{1, \ldots, N\}$, and $\bar{u}_2(k)$, where $k \in \{N+1, \ldots, N+M\}$, can be gathered into vectors $\bar{u}_{1N} \in \mathbb{R}^{3N}$ and $\bar{u}_{1M} \in \mathbb{R}^{3M}$, one for each of the horizons. Finally, the values $\Delta t(k)$, where $k \in \{N + 1, \ldots, N + M\}$, which become variables in the planning horizon, can be gathered into a vector $T_{1M} \in \mathbb{R}$. All variables that describe the complete trajectory from the actual position of the virtual leader until the target region can be collected into the optimization vector $\Omega_L = [\psi_{1N}, \bar{u}_{1N}, \psi_{1M}, \bar{u}_{1M}, T^A_{1M}] \in \mathbb{R}^{7N+8M}$.

The trajectory planning and the dynamic obstacle avoidance problem can then be transformed to minimization of the cost function $J_L(\cdot)$. The function is subject to sets of equality constraints $h(\cdot)$ and inequality constraints $g_{T_a}(\cdot), g_{S_p}(\cdot)$:

$$
\min J_L(\Omega_L), \text{ s.t. } h(k) = 0, \forall k \in \{0, \ldots, N + M - 1\} \\
g_{T_a}(k) \leq 0, \forall k \in \{1, \ldots, N\} \\
g_{T_a}(k) \leq 0, \forall k \in \{N + 1, \ldots, N + M\} \\
g_{S_p}(\psi_1(N + M)) \leq 0
$$

The cost function $J_L(\Omega_L)$ is given by

$$
J_L(\Omega_L) = J_{L, \text{time}}(\Omega_L) + \alpha J_{L, \text{obstacles}}(\Omega_L) \\
= \left( \sum_{k=N+1}^{N+M} \Delta t(k) \right) \\
+ \alpha \sum_{i=1}^{n_o} \min \left\{ 0, \frac{d_{DCH}(\Omega_L, o_i) - R_{DCH}}{d_{DCH}(\Omega_L, o_i)} \right\}^2
$$

The first part, $J_{L, \text{time}}(\Omega_L)$, minimizes the total time to the target region. The second term $J_{L, \text{obstacles}}(\Omega_L)$ is an avoidance function motivated by Stipanović et al. (2007), where a similar approach was used for cooperative collision avoidance in multi-agent systems. In our case, the term $J_{L, \text{obstacles}}(\Omega_L)$ contributes to the final cost when an obstacle is inside the DCH representing the formation. Its value (the penalization) increases as the obstacle approaches the center of the convex hull. The aim of this term is to penalize solutions of the virtual leader trajectory planning in which an obstacle is inside the DCH projected along the trajectory that corresponds to the solution. This is to prevent collisions or breakages of direct visibility between robots by the obstacle. A breakage of direct visibility could interrupt the relative localization necessary for steering the followers. Let us denote the projection of the DCH along the leader’s trajectory $\Omega_L$ as PDCH. An example of PDCH is depicted in Figure 5. The decrease of the penalization value with distance from the center of PDCH and its zero value at the borders of PDCH are required properties necessary for optimization convergence into a feasible solution.

These properties are obtained as follows. The constant $R_{DCH}$ is equal to half of the maximal width of DCH measured in the $x^L$ coordinate. The meaning of $R_{DCH}$ is also denoted in Figures 4 and 5. The function $d_{DCH}(\Omega_L, o_i)$ provides the shortest distance in the direction of the $x^L$ coordinate from the furthest part of obstacle $o_i$ to the borders of PDCH. See the obstacle $o_1$ and the denoted value
In accordance with the leader–follower concept, the trajectory consists of a sequence of transition points and a sequence of constant control inputs applied between the points. The splitting can be realized simply by placing a new transition point at time $t_2$ on the trajectory $\Omega_L(t_1; t_2)$. This transition point is part of both the trajectories arising, which satisfy the constraints in equation (5), except the $g_{SF}(\cdot)$ convergence constraint, which is not satisfied for the $\Omega_L(t_1; t_2)$ part.

Remark 4.1 is important for the convergence analysis of the formation movement into the desired target region presented in Section 5. During the movement, always only a part of the trajectory is followed by the formation in the MPC concept. It is important to show that this splitting is feasible and that the group of robots will approach the target in a sequence of replanning steps of the optimization problem considered in equation (5).

4.4. Trajectory tracking for followers

In accordance with the leader–follower concept, the trajectory of the virtual leader, which is computed as the result of the previous section, is used as an input for trajectory tracking for the followers. First of all, the solution needs to be transformed for each of the following vehicles using the transformation in equation (3). This transformation takes place in the Formation Driving block in Figure 6. The obtained sequences $\psi_L(k) = (\hat{p}_L(k), \hat{\varphi}_L(k))$, where $k \in \{1, \ldots, N\}$, are then utilized as the desired states for the trajectory tracking algorithm with the obstacle-avoidance function for each of the followers (MAVs and UGVs). This approach (realized in the Path Following block in Figure 2) enables responses to events that occur in the environment behind the actual position of the leader, and to incorrect movement of a neighbor in the formation.
Similarly to the leader planning in Section 4.3, the states $\psi_i(k)$ and the control vectors $\dot{u}_i(k)$, where $k \in \{1, \ldots, N\}$, describing the trajectory of the ith follower, can be gathered as vectors $\Psi_i \in \mathbb{R}^{4N}$ and $\dot{u}_i \in \mathbb{R}^{3N}$. The optimization vector $\Omega_i = [\Psi_i, \dot{u}_i] \in \mathbb{R}^{7N}$ is then used to capture the dynamic behavior of the discrete trajectory tracking with a collision avoidance ability as a static optimization process under the receding horizon scheme.

The discrete-time trajectory tracking for each follower is then transformed to an optimization problem with the cost function $J_i(\cdot)$. The function is subject to a number of equality constraints $h_i(\cdot)$ and inequality constraints $g_i(\cdot)$:

$$
\min J_i(\Omega_i), \; i \in \{1, \ldots, n_f\},
$$

s.t. $h_i(k) = 0, \forall k \in \{0, \ldots, N - 1\}$

$$
g_i(k) \leq 0, \forall k \in \{1, \ldots, N\}
$$

The proposed cost function $J_i(\cdot)$ consists of three components with their influence adjusted by constants $\alpha_i$ and $\beta_i$ (set as $\alpha_i = 1$ and $\beta_i = 1$ in the experimental part of this paper):

$$
J_i(\Omega_i) = \sum_{k=1}^{N} \left\| \hat{p}_{d,i}(k) - \bar{p}_i(k) \right\|^2 + \alpha_i \left( \min \left\{ 0, \frac{\text{dist}(\Omega_i) - r_s}{\text{dist}(\Omega_i) - r_a} \right\} \right)^2
$$

$$
+ \beta_i \sum_{j \in \bar{n}_i} \left( \min \left\{ 0, \frac{d_{ij}(\Omega_i, \Omega_j) - r_s}{d_{ij}(\Omega_i, \Omega_j) - r_a} \right\} \right)^2
$$

The first component penalizes deviations of the positions $\bar{p}_i(k)$ from the desired positions $\hat{p}_{d,i}(k), \forall k \in \{1, \ldots, N\}$. As mentioned above, the desired positions are derived from the result of the virtual leader planning using the formation-driving approach presented in Section 3.1. The second term in $J_i(\cdot)$ ensures that dynamic or lately detected obstacles are avoided. The function $\text{dist}(\Omega_i)$ provides the Euclidean distance between the closest obstacle and the follower’s trajectory. The third component of $J_i(\cdot)$ is the sum of the avoidance functions in which the other members of the team are also considered to be dynamic obstacles. This part protects the robots in the case of unexpected behavior of defective neighbors. Function $d_{ij}(\Omega_i, \Omega_j)$ returns the minimal distance between the planned trajectory of follower $i$ and the actually used plan of other followers $j \in \bar{n}_i$, where $\bar{n}_i = \{1, \ldots, i - 1, i + 1, \ldots, n_f\}$. The equality constraints $h_i(\cdot)$ are identical to the equality constraints $h(\cdot)$ in Section 4.3. The inequality constraints $g_i(\cdot)$ are identical to the constraints $g(\cdot)$.

The shape of $J_i(\Omega_i)$ allows the repositioning of followers (UGVs and MAVs) with the aim of obstacle avoidance, compensation for actuator’ and sensors’ uncertainty, or collision avoidance between neighbors. Each UGV follower $i$ can change its position and heading by optimizing its curvature $K_i$ and velocity $v_i$. The MAV followers may also change their altitude $z_i$ by optimizing their ascent velocity $w_i$.

Finally, we should highlight that only the first $n$ control inputs of the obtained solutions $\Omega_i^*$ are used for steering of robots in the MPC concept. The rest of these solutions can be recycled via the Follower Initialization module (depicted in Figure 2) in the next iteration. This approach significantly decreases the computational time required for optimization, since the unused remainder of the solution only needs to be changed due to movement of dynamic obstacles or due to diminishing of disturbances. The influence of the initialization is even more perceivable in the leader trajectory planning. Not only the part of control inputs on the control horizon, but also the complete solution on the planning horizon, can be re-utilized there.

5. Analysis of formation convergence from a feasible initial solution

This section aims to verify that the formation-driving method is capable of navigating the formation into the target region if feasible solutions $\Omega_i^*(\cdot; \cdot)$ and $\Omega_i^*(\cdot; \cdot)$, with $i \in \{1, \ldots, n_f\}$, are known at initial time $t_0$. The initial feasible solutions, which satisfy the constraints given by equations (5) and (8), can be found by the optimization method proposed herein, or provided by a high-level planning system. In particular, this section suggests a proof that the formation will reach the target region with solution $\Omega_i^*(\cdot; \cdot)$ that is always replanned after every $n$ control steps. In addition, it shows that the followers will be stabilized in their positions within the formation by using plans $\Omega_i^*(\cdot; \cdot)$, which are updated with a period of $n$ control steps. This periodic replanning is important for compensation for sensor and actuator uncertainties and for dynamic obstacle avoidance.

We should emphasize that the aim of this section is not to prove convergence to feasible solutions for the optimization problems introduced by equations (5) and (8). The local convergence of these optimization processes is guaranteed by properties of the cost functions, which decrease smoothly and contain local extremes that correspond to sub-optimal trajectories. However, a global optimization method that is always able to find the globally optimal solutions of problems in (5) and (8) in a reasonable amount of time is not available. Therefore, it is not possible to guarantee that feasible initial solutions of problems (5) and (8) will be found even if such feasible solutions do exist.

The aim of this analysis is the specification of the conditions necessary for the reaching of the desired equilibrium by the formation. It enables guaranteeing that the obtained initial plan is feasible for the group. To be able to show the convergence of the entire formation into the desired target region under the approach presented here, let us first specify an assumption on the desired reachability.

Assumption 1. (Desired reachability.) At the initial time $t_0$, there exists a feasible solution of the optimization problem introduced in equation (5). The solution represents the
trajectory for the formation to reach the target region. It guarantees that the trajectory is situated at a sufficient distance from obstacles and that direct visibility between the robots is ensured, which is a crucial aspect of relative localization under the hawk-eye concept. In addition, the utilized optimization method is capable of finding such a solution, which is inside the target region.

Further, we need to show that the following lemmas hold for the cost function introduced in equation (6).

**Lemma 5.1.** Splitting any trajectory \( \Omega_L(t_1; t_3) \) with the beginning at time \( t_1 \) and the end at time \( t_3 \), which satisfies the constraints given in equation (5), into two parts \( \Omega_L(t_1; t_2) \) and \( \Omega_L(t_2; t_3) \), where \( t_1 < t_2 < t_3 \), the following inequality holds: \( J_L(\Omega_L(t_1; t_3)) \leq J_L(\Omega_L(t_1; t_2)) + J_L(\Omega_L(t_2; t_3)) \).

**Proof.** Let us suppose that the new transition point added at time \( t_2 \) (as described in Remark 4.1) lies on the trajectory \( \Omega_L(t_1; t_3) \) between the \( K \)th and \((K + 1)\)th transition points. Thus, \( t_K < t_2 < t_{K+1} \), where \( t_K \) and \( t_{K+1} \) are the times of the \( K \)th and \((K + 1)\)th transition points, respectively.

As introduced in equation (6), the value of the first part of the cost function of \( \Omega_L(t_1; t_3) \) is obtained as

\[
J_{L,\text{time}}(\Omega_L(t_1; t_3)) = N \Delta t + \sum_{k=N+1}^{N+M} \Delta t(k) \tag{10}
\]

If \( K < N \), which means that the new transition point is placed within the interval \( T_N \), the first part of the cost function of the split trajectories can be expressed as

\[
J_{L,\text{time}}(\Omega_L(t_1; t_2)) = K \Delta t + (t_2 - t_K) \tag{11}
\]

and

\[
J_{L,\text{time}}(\Omega_L(t_2; t_3)) = (N - K - 1) \Delta t + (t_{K+1} - t_2) + \sum_{k=N+1}^{N+M} \Delta t(k) \tag{12}
\]

Combining equations (10), (11), and (12) together with equation \( \Delta t = t_{K+1} - t_K \), we can write

\[
J_{L,\text{time}}(\Omega_L(t_1; t_2)) + J_{L,\text{time}}(\Omega_L(t_2; t_3)) = K \Delta t + \Delta t + N \Delta t - K \Delta t - \Delta t + \sum_{k=N+1}^{N+M} \Delta t(k) = J_{L,\text{time}}(\Omega_L(t_1; t_3)) \tag{13}
\]
If $K \geq N$, which means that the new transition point is placed within the interval $T_K$, the first part of the cost function of the split trajectories can be expressed as

$$J_{\text{L, time}}(\Omega_L(t_1; t_2)) = N \Delta t + (t_2 - t_K) + \sum_{k=K+1}^{K-1} \Delta t(k)$$  \hspace{1cm} (14)$$

and

$$J_{\text{L, time}}(\Omega_L(t_2; t_3)) = (t_{K+1} - t_2) + \sum_{k=N+1}^{N+M} \Delta t(k)$$  \hspace{1cm} (15)$$

Considering equations (10), (14), and (15) together with equation $\Delta t(K) = t_{K+1} - f_k$, we can again write

$$J_{\text{L, time}}(\Omega_L(t_1; t_2) + J_{\text{L, time}}(\Omega_L(t_2; t_3)) = N \Delta t + \Delta t(K)$$

$$+ \sum_{k=K+1}^{K-1} \Delta t(k) + \sum_{k=K+1}^{K+1} \Delta t(k)$$

$$= J_{\text{L, time}}(\Omega_L(t_1; t_3))$$  \hspace{1cm} (16)$$

The second part of the cost function of $\Omega_L(t_1; t_3)$ is expressed as

$$J_{\text{L, obstacles}}(\Omega_L(t_1; t_3))$$

$$= \sum_{l=1}^{m_o} \left( \min \left\{ 0, \frac{d_{\text{DCH}}(\Omega_L(t_1; t_3), o_l)}{d_{\text{DCH}}(\Omega_L(t_1; t_3), o_l) - R_{\text{DCH}}} \right\} \right)^2$$  \hspace{1cm} (17)$$

and similarly

$$J_{\text{L, obstacles}}(\Omega_L(t_1; t_2) + J_{\text{L, obstacles}}(\Omega_L(t_2; t_3)) =$$

$$= \sum_{l=1}^{m_o} \left( \min \left\{ 0, \frac{d_{\text{DCH}}(\Omega_L(t_1; t_2), o_l)}{d_{\text{DCH}}(\Omega_L(t_1; t_2), o_l) - R_{\text{DCH}}} \right\} \right)^2$$

$$+ \sum_{l=1}^{m_o} \left( \min \left\{ 0, \frac{d_{\text{DCH}}(\Omega_L(t_2; t_3), o_l)}{d_{\text{DCH}}(\Omega_L(t_2; t_3), o_l) - R_{\text{DCH}}} \right\} \right)^2$$  \hspace{1cm} (18)$$

As already mentioned, obstacles contribute to the cost function if they are placed inside the DCH projected along the trajectory. It is clear that obstacles appearing in the projection of DCH along $\Omega_L(t_1; t_2)$ must also contribute with the same value in one of the split parts. Therefore, the value of the sum $J_{\text{L, obstacles}}(\Omega_L(t_1; t_2)) + J_{\text{L, obstacles}}(\Omega_L(t_2; t_3))$ cannot be smaller than $J_{\text{L, obstacles}}(\Omega_L(t_1; t_3))$. Nevertheless, it may happen that an obstacle appears in the projection of DCH along both parts, since these can overlap (e.g. in a sharp turn of the trajectory, as shown in Figure 5). In this case, the obstacle contributes to the cost functions twice and the value of the sum is increased. This multiple appearance is eliminated in $J_{\text{L, obstacles}}(\Omega_L(t_1; t_3))$ as follows. To obtain the value of the function $d_{\text{DCH}}(\Omega_L(t_1; t_3), o_l)$, the shortest distance from the border of DCH projected along $\Omega_L(t_1; t_2)$ to obstacle $o_l$ in the direction of the $x^1$ coordinate has to be computed. If obstacle $o_l$ occurs in the projection of DCH multiple times (e.g. like obstacle $o_2$ in Figure 5), all the shortest distances have to be obtained. The value of the function $d_{\text{DCH}}(\Omega_L(t_1; t_3), o_l)$ is then the largest value from the set of these shortest distances.

Considering these observations together with equation (13) and equation (16), we can conclude that

$$J_L(\Omega_L(t_1; t_3)) \leq J_L(\Omega_L(t_1; t_2)) + J_L(\Omega_L(t_2; t_3))$$  \hspace{1cm} (19)$$

**Lemma 5.2.** Splitting any trajectory $\Omega_L(t_1; t_3)$, with $t_1 < t_3$ and which satisfies the constraints given in equation (5), at the time $t_T$ of entering into the target region, the following inequality holds: $J_L(\Omega_L(t_1; t_3)) \geq J_L(\Omega_L(t_1; t_T))$.

**Proof.** Since the trajectory $\Omega_L(t_1; t_3)$ satisfies the constraints in equation (5), the following inequality holds: $t_1 < t_T \leq t_3$.

If $t_T = t_3$, one can directly write that $J_L(\Omega_L(t_1; t_3)) = J_L(\Omega_L(t_1; t_T))$.

If $t_T < t_3$, considering equation (10) for $t_2 := t_T$, and the evident fact that $J_{\text{L, time}}(\Omega_L(t_T; t_T)) > 0$ (see for example equation (12)), one can write that $J_{\text{L, time}}(\Omega_L(t_1; t_3)) > J_{\text{L, time}}(\Omega_L(t_1; t_T))$. Taking into account the fact that only the obstacles contributing to $J_{\text{L, obstacles}}(\Omega_L(t_1; t_3))$ may also contribute to $J_{\text{L, obstacles}}(\Omega_L(t_1; t_T))$, one can write that $J_{\text{L, obstacles}}(\Omega_L(t_1; t_3)) \geq J_{\text{L, obstacles}}(\Omega_L(t_1; t_T))$. Combining the inequalities for $J_{\text{L, time}}$ and $J_{\text{L, obstacles}}$, we obtain the inequality $J_L(\Omega_L(t_1; t_3)) > J_L(\Omega_L(t_1; t_T))$ for situations with $t_T < t_3$.

**Remark 5.3.** Considering Remark 4.1 and Lemma 5.2, we can conclude that by splitting any trajectory, which satisfies the constraints in equation (5), at the time of crossing the border of the target region a feasible solution of the formation to the target region problem, evaluated by a lower (or the same) value of the cost function, is obtained.

Now, we are prepared to show the convergence of the formation into the target region.

**Theorem 5.4.** Under Assumption 1, having a feasible solution of the problem in equation (5) at time $t_0$, the formation is guided by the MPC scheme towards the target region if the inequality $D(k) < J_L(\Omega_L(\tau; n \Delta t + \tau^*))$, where $\tau = kn \Delta t + t_0$, $k \in \mathbb{Z}^+$, and $k < (t_T - t_0)/n \Delta t$, is satisfied. $D(k)$ denotes the perturbations on $J_L(\Omega_L(\cdot; \cdot))$ and $t_T$ is the time at which the formation approaches the target region.

**Proof.** Being inspired by the theory of nonlinear systems in Chapter 4 of Khalil (2001), we can prove the convergence of the formation into the target region if we show the decrease in the value of the cost function introduced in equation (6) over time. This means that we have to show the conditions in which the following inequality holds:

$$J_L(\Omega_L(n \Delta t + \tau; t_T^*)) - J_L(\Omega_L(\tau; t_T^*)) < 0$$  \hspace{1cm} (20)$$
In this equation, the term $J_L(\Omega_\ell(\cdot;\cdot)^\circ)$ is the cost of the solution found by the optimization method. The vector $\Omega_\ell(\tau; t_1)^\circ$ represents the computed trajectory of the virtual leader with the beginning at time $\tau$ and the end at time $t_1$. The term $J_L(\Omega_\ell(n\Delta t + \tau; t_2)^\circ)$ represents the cost of the optimization vector found in the next control step. This solution is used after applying the first $n$ elements of the trajectory with the beginning at time $\tau$. Using an ideal optimization method, which is always capable of finding the global optimal solution, both solutions would end directly on the border of the target region. Any trajectory containing a part inside the target region may not be optimal, which is obvious from Remark 5.3 and Lemma 5.2. With real optimization algorithms working in a finite time, it is impossible to find the global optimal solution. The obtained solutions that satisfy the constraints from equation (5) always terminate inside the target region (not exactly on the border). The length of the part of the trajectory inside the desired target region can differ in each planning step of the MPC algorithm. Therefore, we have to omit this part inside the region to be able to show the convergence of the formation to the target region by analyzing the contraction of the trajectory between consecutive MPC planning steps.

This means that we have to split the trajectories $\Omega_\ell(\tau; t_1)^\circ$ and $\Omega_\ell(n\Delta t + \tau; t_2)^\circ$ at the time when they enter the target region. In Remarks 4.1 and 5.3 and Lemma 5.2 it is shown that such shortened trajectories satisfy the constraints from equation (5), and they represent solutions of the optimization problem with lower values for the cost function. Equation (20) may then be rewritten as

$$J_L(\Omega_\ell(n\Delta t + \tau; t_2)^\circ) - J_L(\Omega_\ell(\tau; t_1)^\circ) < 0 \quad (21)$$

where $t_{T_1}$ and $t_{T_2}$ are the time instants at which the trajectories $\Omega_\ell(\tau; t_1)^\circ$ and $\Omega_\ell(n\Delta t + \tau; t_2)^\circ$ enter the target region. Further, let us split the trajectory $\Omega_\ell(\tau; t_1)^\circ$ at time $n\Delta t + \tau$, as shown in Remark 4.1. Using Lemma 5.1, we can write that

$$J_L(\Omega_\ell(\tau; t_{T_1})^\circ) \leq J_L(\Omega_\ell(\tau; n\Delta t + \tau)^\circ) + J_L(\Omega_\ell(n\Delta t + \tau; t_{T_1})^\circ) \quad (22)$$

Combining equations (21) and (22) we obtain

$$-J_L(\Omega_\ell(\tau; n\Delta t + \tau)^\circ) - J_L(\Omega_\ell(n\Delta t + \tau; t_{T_1})^\circ) + J_L(\Omega_\ell(n\Delta t + \tau; t_{T_2})^\circ) < 0 \quad (23)$$

Let us substitute

$$-J_L(\Omega_\ell(n\Delta t + \tau; t_{T_1})^\circ) + J_L(\Omega_\ell(n\Delta t + \tau; t_{T_2})^\circ) := D(k) \quad (24)$$

into equation (23), so that we obtain the inequality $D(k) < J_L(\Omega_\ell(\tau; n\Delta t + \tau)^\circ)$, which represents limits on perturbations. The inequality is satisfied if the formation is outside the target region, which agrees with the limitation $\tau = kn\Delta t + t_0$, where $k \in \mathbb{Z}^+$ and $k < (\bar{t} - t_0)/n\Delta t$, as stated in Theorem 5.4.

5.1. Analysis of results of the convergence proof

The aim of this subsection is to show the meaning of the perturbations $D(k)$ and a practical utilization of the results of the convergence analysis presented in the previous section.

Analyzing equation (24), one can see that perturbations $D(k)$ represent changes (usually an increase) in the values of the cost function that evaluates the trajectories found in two consecutive MPC planning steps. The trajectories, both beginning at time $n\Delta t + \tau$ and ending on the border of the target region, are found by the optimization method, one at time $\tau$ and one at time $n\Delta t + \tau$.

1) Let us first consider a situation without dynamic or unknown obstacles. In this case, the increase of the value of the second term of the cost function (6) may be neglected: $J_{L,\text{obstacles}}(\Omega_\ell(n\Delta t + \tau; t_{T_2})) - J_{L,\text{obstacles}}(\Omega_\ell(n\Delta t + \tau; t_{T_1})) = 0$, and $D(k) = J_{L,\text{time}}(\Omega_\ell(n\Delta t + \tau; t_{T_2})^\circ) - J_{L,\text{time}}(\Omega_\ell(n\Delta t + \tau; t_{T_1})^\circ)$. The perturbations are therefore caused mainly by imprecise actuators and by the simplification of the kinematic model. This results in deviations in the position of the formation after each MPC step. These deviations need to be compensated for, and they prolong the total time to the goal by the time difference $T_2 - T_1$. In situations without dynamic or unknown obstacles, this time difference is approximately equal to the value $D(k)$. Considering Theorem 5.4 and the obvious fact that $J_{L,\text{obstacles}}(\Omega_\ell(\tau; n\Delta t + \tau)^\circ) \geq 0$, it has to be ensured that

$$D(k) < n\Delta t \quad (25)$$

It can be seen that the value of the cost function is decreasing and the plant converges to the desired target region. This inequality is important for practical utilization of the method.

2) In the presence of dynamic obstacles or suddenly detected obstacles, the difference $J_{L,\text{obstacles}}(\Omega_\ell(n\Delta t + \tau; t_{T_2})) - J_{L,\text{obstacles}}(\Omega_\ell(n\Delta t + \tau; t_{T_1}))$ may be the dominant part of the perturbations. Equation (25) may then be violated even if the uncertainty of the actuators is sufficiently small. In this case, the convergence to the target region is temporarily broken, which can be detected by the increase in the cost function value. In real-world applications, it is sometimes necessary to allow a temporary increase in the value of the cost function. For example, newly detected obstacles can be avoided by the replanning included in the MPC concept, and the convergence is restored. A problem occurs in the presence of dynamic obstacles that push, by their influence via the cost function, the overall formation from the target region. If such a situation is detected by long-term growth of the value of the cost function, the formation has to stop and the planning process needs to be restarted.
5.2. Analysis of the stability of the followers in their desired positions within the formation

The stability of the formation in the desired shape is solved through the distribution of transformed states of the virtual leader using the formation-driving concept in Barfoot and Clark (2004), extended here to the 3D case (see Section 3.1). Using this approach, the formation stabilization is transformed into the independent trajectory tracking processes running onboard the following robots. The classical MPC approach is then employed for trajectory tracking with the obstacle- and failing-neighbor-avoidance functionalities. It is not the aim of this paper to analyze the performance of the standard trajectory tracking mechanism, but we would like to point out the overall behavior of the formation. Again, let us highlight that it is not the aim of this analysis to show the convergence of the optimization problem described in equation (8). The aim is to specify the conditions for which the shape of the formation remains stable (followers follow their desired position behind the virtual leader) using periodically replanned results of the problem in equation (8).

In an ideal state without perturbations due to dynamic obstacles, actuator uncertainties, and sensor uncertainties, the equality \( J_i(\Omega_1(\cdot \cdot \cdot \cdot) = 0 \) holds. As shown for example in Figure 7, the value of the cost function is increased if a robot deviates from its desired position (the first term of equation (9) contributes) or if an obstacle or a neighbor is in close proximity to the robot (the second term of equation (9) contributes). Based on the values of the cost function, one can decide that a follower or a group of followers has broken away from the formation, and has to be considered as an independent object/sub-formation. An approach similar to the concept utilized for the formation navigation presented in Section 4.3 may be used for such a sub-formation to rejoin the group. This concept may be employed if it is enabled by the relative localization (the robot is still within the field of view of MAVs acting as hawk eyes) and by the communication range. In this case, the area around the desired position within the former formation has to be considered the target region. The sub-formation is then controlled using the approach presented in Section 4, where only the members of the unstuck group are considered in the convex hull representing the formation. If only a single robot is unstuck, the convex hull is reduced to a circle with radius equal to the detection radius \( r_s \).

Theorem 5.4 and the related proof can be utilized for the convergence analysis, similarly to what was done for the static target region. Only the practical meaning of the perturbations \( D(k) \) is changed. The uncertainty of the actuators and the imprecise kinematic model are still included in the perturbations according to equation (24). Nevertheless, the prolonged total time to the goal given by the time difference \( T_2 - T_1 \) is caused mainly by the movement of the former formation, which is followed by the new formation. To better understand the problem, let us split the perturbations into two parts: \( D(k) \), which represents the perturbations given by the imprecise actuators and model, and \( D_{\text{drift}}(k) \), which includes the influence of the drift of the dynamic target region (the required place of the unstuck followers in the former formation). The equation \( D_{\text{total}}(k) = D(k) + D_{\text{drift}}(k) \) holds for the situation with the dynamic target region, whereas, in the analysis in the previous sub-section, the equations \( D_{\text{drift}}(k) = 0 \) and \( D_{\text{total}}(k) = D(k) \) hold.

During the MPC step with duration \( n\Delta t \), the dynamic target region moves over the distance \( v_{\text{target}}n\Delta t \) in the worst case. The symbol \( v_{\text{target}} \) denotes the maximum speed of movement of the former formation, and therefore also the maximum speed of the dynamic target region. This displacement prolongs the expected time to the goal by the time difference \( v_{\text{target}}n\Delta t/v_{\text{unstuck}} \), where \( v_{\text{unstuck}} \) is the maximal feasible speed of the unstuck formation/robot. For the dynamic target region, the requirement on the perturbations given by the imprecise actuators and model (for the static target region presented in equation (25)) can be expressed as

\[
D(k) < n\Delta t - n\Delta t \frac{v_{\text{target}}}{v_{\text{unstuck}}}
\]

### 6. Experimental results

In this section, we demonstrate the performance of the method presented here, and we experimentally verify the theoretical results introduced in Section 5. The response of the planning and control mechanisms to the detected static and dynamic obstacles, and also to failures of neighbors in the formation, is shown in the addressed robotic scenarios. The experiment with real robots and the computational time analysis reflect the applicability of the system. Movies of simulations and experiments are attached to this paper and can be found at Saska (2013).

The presented results were obtained using the proposed algorithm with the following parameters: \( n = 2, N = 4, M = 6, \alpha = 1, \alpha_i = 1, \beta_i = 1, \) and \( \Delta t = 0.25 \) s. We employed sequential quadratic programming (SQP) (Nocedal and Wright, 2006) to solve the optimization problems used in the virtual leader trajectory planning and for the stabilization of followers. This solver provided the best performance among the available evaluated algorithms. However, any optimization method which is able to solve the optimization problems defined in this paper can be used.

The map of the environment, the position of the target region, and the desired shape of the formation are always known at the beginning of the missions in the experiments. The positions of dynamic obstacles are unknown.

In the first experiment presented in this section, a formation of 11 followers (eight UGVs and three MAVs) has to move into a target region through an environment with two overhead obstacles and one dynamic obstacle. See Table 3 for the parameters of the formation and Figure 6 for snapshots of the experiment. Figure 7 illustrates the progress of
the values of the cost function used for the virtual leader’s trajectory planning (equation (6)) and the values of the cost function employed for the stabilization of the followers (equation (9)).

The initial position of the formation and the trajectory obtained in the first planning loop of the presented MPC algorithm are shown in Figure 6(a). The snapshots in Figure 6(b) demonstrate the ability of the formation stabilization algorithm to autonomously modify the desired shape of the group if this is necessary due to restrictions given by the robots’ workspace. The pictures show the response of the followers’ planning algorithm to the narrow entrance and the consequent temporary shrinking of the formation.

In Figure 6(c) and 6(d), the formation passes by obstacles that verify the ability of the approach to keep direct visibility between team members. Although the UGVs could pass under the obstacles and the MAVs could fly over them (which would decrease the time to the goal), the planned trajectory leads around the obstacles to keep them outside the convex hull representing the formation. The UGVs may partly pass under the obstacles, with the aim to follow the trajectory that is as short as possible according to the optimization problem specified in equation (5).

A response of the trajectory planning algorithm to obstacles that suddenly appear is shown in Figure 6(e), where a new obstacle was detected. Finally, dynamic obstacle avoidance behavior of the method is shown in Figure 6(f). In this situation, the virtual leader’s planning algorithm could not respond to the movement of the obstacle behind the position of the virtual leader. Therefore, the followers are forced via the avoidance function in equation (9) to deviate temporarily from their desired positions within the formation.

The results of a statistical test of the performance of the algorithm are presented in Table 4. The aim is to show the reliability and the practical utilization of the method with different values of parameter $M$, whose proper setting is crucial for the deployment of the system. For the test, a set of 1000 positions for the target region was randomly generated in the free space on the right side of the workspace introduced in Figure 6(a). The algorithm was tested with different values of $M$ for each of these configurations of the target, using Intel Core Duo CPU, 3.2 GHz, 4 GB RAM.

Fig. 9. An example of the trajectories followed by a formation of four followers (three UGVs and one MAV). The MAV follows the virtual leader, while it descends to avoid the top obstacle.

The simulations are counted as successful if the formation reached the desired target region without collisions and with relative visibility kept during the entire movement. The total time to reach the goal indicates the quality of the solutions.

The most time-consuming part of the proposed MPC approach is evaluation of the objective function in equation (6). This function is recalled in each iteration of the optimization process. The second term of the function, which implements the obstacle avoidance, represents a major contribution to the computational demands. In particular, two variables influence the computational complexity of the formation-driving system that is proposed here: the number of obstacles considered for the planning, and the dimension of the optimization vector. Figure 8 shows that the mean computational time linearly depends on the number of obstacles. This confirms the expectations, since the distance from the convex hull is computed separately for each of the obstacles only in the second term of equation (6). The distance-to-obstacle calculation is the most computationally intensive part of the algorithm.

The length of the optimization vector predominantly affects the number of iterations of the optimization process. The mean computational time of the planning process exponentially depends on the length of the optimization vector (see experimental results in Figure 8 and analysis of quadratic programming algorithms in Nocedal and Wright, 2006).

The simulation presented in Figure 9 shows the performance of the algorithm in the situation where an obstacle (the traverse beam under the ceiling) blocks the MAV follower from reaching the desired target region at the desired altitude ($h_i$ coordinate). Similarly to the previous experiment, where the formation passed a narrow corridor, the formation is forced to change its desired shape temporarily.

The experiment presented in Figure 10 demonstrates the ability of the method to avoid collisions between the robots in the formation. To show this functionality, the failure of a follower (its steering was blocked) was simulated to show the failure tolerance and the robustness of the system. The snapshots show successful avoidance maneuvers of neighboring followers as a response to predictions of possible collisions (see the last part of equation (9) for details on the applied avoidance function).

In the real experiment presented in Figure 11, a formation of three ground robots and one helicopter has to move from its initial locations into the desired target region. The trajectory planning method presented in this paper was employed to practically verify the usefulness of the visual relative localization and consequently the stabilization of followers from flying robots. Two different UGVs, one G2Bot platform (Chudoba et al., 2006) (the bigger robot in Figure 11) and two MMP5 platforms are used in this experiment. To verify the concept of the proposed 3D formations, an Ar.Drone quadrocopter is used as a flying follower. The MAV is equipped with a vision system to be able to follow the proposed hawk-eye approach. It carries a bottom monocular camera supplemented by a vision algorithm (Saska et al., 2012a) that is able to identify the location and the size of the color markers of the UGVs in the image.
This information is used for the relative localization of all members of the formation. The estimated relative positions from such hawk eyes are sent to the UGV followers over a WiFi link as feedback to maintain the predefined formation shape.

Beside the pictures of the experiment, a GUI monitoring the formation deployment in the reconnaissance applications is shown in Figure 11, on the right side. The GUI shows pictures from the cameras carried by all followers and a schematic map of the environment. The MAV camera is primarily designated as the hawk eye. Additionally, it provides a general overview of the scene for the supervisor of the mission. The UGVs’ cameras are employed for reconnaissance purposes. The actual plan of the virtual leader found by our approach and the history of the leader’s movement are also depicted in the map. The position of the virtual leader is estimated from the odometry of the G2Bot follower, which is intentionally placed in the same position as the virtual leader.

The experiment in Figure 12 demonstrates the ability of the obstacle avoidance by temporarily shrinking the formation. In the experiment, the Pioneer 3-AT robotic platform with a mobile heliport, two MMP5 platforms and the Ar.Drone MAV act as followers. The positions of the outer UGVs within the formation are autonomously changed as a result of the multi-criteria cost function (the first and the second term of $J_i(\cdot)$ contribute in an antagonistic way) to pass safely through the narrow corridor.

The onboard visual localization, which was used in the experiments, provides relative positions of robots at a frame rate of 10–30 Hz (Faigl et al., 2013). This is significantly less than the update rates provided by motion-capture systems (e.g. Vicon), which are often used for stabilization of MAV groups. Therefore, a MAV low-level stabilization and limits on the maximal speed of robots have to be employed with the onboard localization. Internal stabilization of the Ar.Drone platform based on optical flow obtained from the bottom camera and the inertial measurement unit were used in the experiments. For details, software implementation, and interfacing with Ar.Drone, see Krajnik (2013).

7. Conclusion

A control methodology developed for formation driving of 3D heterogeneous MAV–UGV formations stabilized via hawk-eye-like visual localization is presented in this paper.
A novel MPC scheme is introduced with an integrated obstacle-avoidance function that ensures direct visibility between MAVs and UGVs. Visibility between MAVs and UGVs is crucial for the top-view relative localization of the team members. This may act as an enabling technique for real-world deployment of formations of micro-scale robots. Our experiments show the performance of the method and verify its robustness in an environment with dynamic obstacles. In addition, the requirements for practical utilization of the method are specified by sound theoretical analyses. As a result of these analyses, we propose a simple mechanism to detect and tackle eventual violations of the convergence of the 3D formation’s movement into the target region.

The main contributions of this paper from the perspectives of control, formation driving, and robotics in general are the following:

1. Top-view visual relative localization, which enables the deployment of teams of MAVs and simple ground robots in environments without any pre-installed global localization infrastructure.
2. The novel MPC approach with an additional planning horizon, which is crucial for incorporating global trajectory planning and local control. In addition, this approach enables the inclusion of constraints given by the top-view relative localization of heterogeneous formations.
3. An extended leader–follower concept with a novel representation of 3D formations that satisfies the requirements of direct visibility between the team members.

**Appendix: Low-level controller designed for Ar. Drone**

In the kinematic model described in Section 3, it is assumed that the MAVs can follow a trajectory containing segments with a given curvature. Further, we assume that MAVs...
are controlled using forward speed $v$, curvature $K$, and ascent $w$. We used the Ar.Drone quadrocopter, which allows changes in the speed of its rotors and consequently its pitch, yaw, and roll angles (see Figure 1(b) for the definition of the angles).

The forward speed of the drone can be controlled by changing the pitch $\theta$. Let us assume the simplified model of the quadrocopter depicted in Figure 13. Force $F$ is generated by the rotors. $F_g$ denotes the gravitational force. The forward force is then $F_o = -F_g \tan \theta$. Assuming that the drone moves slowly, we can use an approximation $F_o = c_0 v$, where $c_0$ is a constant that may be simply identified experimentally. The forward speed of the drone is then controlled by changing pitch $\theta$:

$$\tan \theta = -\frac{c_0 v}{F_g} \quad (27)$$

When the drone moves along a circular segment, the centrifugal force has to be compensated for by changing roll $\eta$. The centrifugal force can be expressed as $F_c = m v^2 / r$, where $m$ is the weight of the drone and $r = 1/K$ is the radius of the circular segment with curvature $K$. The centrifugal force is compensated for by the lateral force $F_d = -F_c$. $F_d$ is controlled by changing roll as $F_d = -F_g \tan \eta$, which gives $-F_g \tan \eta = m v^2 / r$. The lateral speed is then controlled by

$$\tan \eta = -\frac{v^2 K}{g} \quad (28)$$

When the pitch and roll angles are small, the approximation $\tan x \sim x$ can be used in (27) and (28). To control the drone along a trajectory with the given curvature $K$ and known forward speed $v$, pitch $\theta$ and roll $\eta$ are controlled. Further details on Ar.Drone control can be found in Krajnik et al. (2011).
